## CUMULATIVE FATIGUE DAMAGE OF AXIALLY LOADED ALCLAD 75S-T6

## AND ALCLAD 24S-T3 ALUMINUM-ALLOY SHEET

By Ira Smith, Darnley M. Howard, and Frank C. Smith

## SUMMARY

This report presents the results of cumulative-fatigue-damage tests made on 607 specimens machined from alclad 75S-T6 aluminum-alloy sheet 0.064 inch thick and 198 specimens of alclad 24S-T3 and alclad 75S-T6 aluminum-alloy sheet 0.032 inch thick. The tests of the 0.064-inch-thick specimens consisted of 35 different loading conditions and the tests of the 0.032-inch material consisted of 13 different loading conditions. The stress amplitudes used were nominally  $\pm 16,000$  and  $\pm 17,000$  psi,  $\pm 16,000$  and  $\pm 30,000$  psi,  $\pm 16,000$  and  $\pm 60,000$  psi,  $\pm 30,000$  and  $\pm 40,000$  psi, and  $\pm 30,000$  and  $\pm 60,000$  psi.

The cumulative-damage ratio was calculated as the sum of the ratios of the numbers of cycles applied at the different stress levels to the number of cycles at the same stress level that would cause failure. Seventy-two percent of the average cumulative-damage ratios were within twenty percent of unity, and forty percent were within ten percent of unity. The smallest average cumulative-damage ratio of a group of four similar specimens was 0.568 and the largest, 1.440. The cumulative-damage ratios for the 0.032-inch-thick material showed no systematic variation from those for the 0.064-inch material.

## INTRODUCTION

Aircraft structures in service are subjected to stresses of varying amplitudes. It is desirable, therefore, to include the effect of varying stress amplitude in tests for determining the fatigue life of aircraft. It is known (refs. 1 and 2) that, for some ferrous materials, a sequence of stresses of fluctuating amplitude produces pronounced effects on the fatigue properties of these materials. The effects of understressing, overstressing, "coaxing," and sequence loading have been investigated for ferrous materials (refs. 3 to 7). Relatively little work of this type, however, has been done on high-strength aluminum alloys.

Several theories have been advanced in an effort to obtain a relationship between the number of cycles of stress at different stress levels

and the cumulative fatigue damage. Miner (ref. 8) assumed the amount of cumulative fatigue damage under repeated loads at a given stress level to equal the number of loading cycles applied at that stress level expressed as a percentage of the number of cycles to failure at that stress level. A review of previous work led Richart and Newmark (ref. 9) to assume the existence of a damage - cycle-ratio relation during the process of forming a fatigue crack at any overstress. The relationship, in the form of experimentally determined curves, is used to predict damage and failure. Wallgren (ref. 10) assumed a modified expression of the cumulative-damage hypothesis of reference 8 in considering that the sum of the cycle ratios at failure can exceed or fall below unity depending on the material and cycle pattern.

The National Bureau of Standards, under the sponsorship and with the financial assistance of the National Advisory Committee for Aeronautics, undertook a program of cumulative-fatigue-damage tests on high-strength aluminum-alloy sheet materials to obtain sufficient experimental evidence to determine the usefulness of Miner's method described in reference 8. The present investigation was performed in two parts. The first part consisted of tests of 0.064-inch-thick alclad 75S-T6 aluminum-alloy rolled sheet specimens. The data obtained compare cumulative fatigue damage over a wide range of stress-cycle histories. The second part consisted of tests of 0.032-inch-thick alclad 24S-T3 and 0.032-inch-thick alclad 75S-T6. The results of these tests are included to show the effect on the cumulative damage ratio of:

- (1) Stress amplitude
- (2) Sheet thickness
- (3) Material
- (4) Mean stress

The authors wish to express their appreciation to the staff of the Engineering Mechanics Section of the National Bureau of Standards for their assistance on this work. Particular thanks go to Mr. Timothy O'Connor for his assistance on the tests and to Mr. Samuel Levy and the late Mr. A. E. McPherson for their advice, assistance, and encouragement.

#### DESCRIPTION OF MACHINES

The tests were performed on two nominally identical lever-type fatigue testing machines (fig. 1) designed and constructed at the National Bureau of Standards (ref. 11). These machines operate at a nominal speed of 1,000 rpm and are capable of automatically applying a periodic sequence of loads of two amplitudes for various predetermined loading patterns. The eccentric crank (fig. 2) is placed in either of two predetermined positions by means of a compressed-air actuated linkage. The air valves

are controlled through a suitable circuit closed by microswitches. After the preset number of cycles has been reached, a disk with lugs driven by a gear reduction box (fig. 3) actuates the microswitches. Specimens are tightly clamped between the jaws and are axially loaded. A desired mean stress is obtained by suitably setting the position of the lever relative to the midpoint of its excursion before the specimen is clamped. Load is measured in terms of bending strain in the lever by means of two wire resistance strain gages located near the extreme fibers of the lever. The output from these gages is passed into a modified SR-4 circuit (ref. 12) which drives a cathode-ray oscilloscope. This circuit gives a continuous indication of the force-time relationship in the specimen.

#### SPECIMENS AND TEST PROCEDURE

The specimens for the cumulative-fatigue-damage tests were machined from alclad 75S-T6 aluminum-alloy rolled sheet 0.064 inch thick and from alclad 24S-T3 and alclad 75S-T6 aluminum-alloy sheet 0.032 inch thick. The static properties of the materials are shown in figure 4.

The specimens were machined to the shape shown in figure 5. Lubricated steel guides (ref. 13) were used to prevent the specimens from buckling during the compression half of the loading cycle.

Since the effects of cumulative damage on the fatigue life of aluminum alloys may be small, it was felt that extreme care should be used to obtain as consistent fatigue data as possible. In an effort to achieve consistent data the following fundamental variables affecting scatter were considered:

- (a) The homogeneity of the material from which the specimens were made
- (b) The consistency of the machining technique used to manufacture the specimens
- (c) The actual size of the specimens after machining, with particular emphasis on the area of the reduced section
- (d) The general appearance of the surface of the specimen immediately before testing with regard to any scratches, nicks, or other accidentally introduced stress-raiser
- (e) The magnitude and distribution of the stress applied to the reduced section of the specimen

In addition to these variables there are, no doubt, many other factors which influence the fatigue life, such as corrosion, systematic

(but unknown) variations in the testing machines, and variations in testing technique. The test program was designed to control the above variables as well as possible.

To minimize variations in the results, all specimens in a given test group were machined from the same sheet of material. A test group consisted of 16 specimens selected from a batch of 22 machined simultaneously. Before testing, each specimen was visually examined for any obvious stress-raiser and if such were found the specimen was rejected. The two outside specimens of each batch, which were burried as a result of machining, were always discarded. Corners of the reduced section of each specimen were rounded lightly by hand with No. 0 emery paper.

The strain distribution across two typical specimens was checked with Tuckerman optical strain gages during the course of the tests and was found uniform to within 1 percent. The calibration of the machines was checked after each test group. The calibration constants did not change more than 1.5 percent between calibrations. The dynamic load was measured on each specimen and on most specimens at least twice during the test. The assembly of specimen, guides, paper, and lubricants was a modification of that described in reference 13. For the first tests, performed at stresses of  $\pm 30,000$  and  $\pm 40,000$  psi, the paper was omitted and extreme care taken to eliminate possible binding of the guides with the specimen. This method was discarded and the following procedure adopted for the remaining tests.

Two strips of copy paper 1 inch wide were soaked for 5 minutes in SAE 40 motor oil. The guide blocks and specimen were covered with a thin coat of Andok M-275 cup grease. The greased blocks were clamped against either side of the specimen with the oiled paper between guide and specimen. The clamp was tight enough to prevent the specimen from sliding under normal hand pressure. The assembly remained clamped for at least 5 minutes to allow grease to squeeze out that would otherwise come out during the course of the test. The guides were loosened, adjusted, and locked. Guides on all specimens were adjusted so that when the specimen was held vertically the guide would not slide under its own weight but would slide under the additional weight of a 0.44-pound jig. The weight of the guide assembly was 0.49 pound. Figure 6 shows a typical specimen ready for test.

The cycle pattern for a given group of tests specifies the number of cycles which the testing machine automatically applies at the first of the two amplitudes for which it is set before switching to the other. The order of tests in each complete test group of 16 specimens for a given cycle pattern was as follows:

- (1) A test at the higher stress
- (2) A dual-load test applying the higher stress first

- (3) A test at the lower stress
- (4) A dual-load test applying the lower stress first

This sequence of tests was repeated four times. As a check on possible changes in testing technique of a particular operator with time, one out of every four specimens was tested by an alternate operator.

#### METHOD OF ANALYSIS

Fatigue tests were performed on 805 specimens in 52 test groups. A normal test group consisted of 16 tests, 4 each to failure at the higher and lower stresses and 8 cumulative-fatigue-damage tests, 4 with the higher stress applied first and 4 with the lower stress applied first. In some cases a test group was used to check or duplicate earlier tests and thus show the scatter between groups. In a few other cases a single test group was used for two loading conditions.

The data were analyzed using Miner's theory (ref. 8). This theory assumes a linear relationship between the amount of damage done to the material at a certain fatigue stress and the number of cycles applied at that stress. It assumes that previous stress history has no effect on the linearity of the relationship. It can be shown that, using these assumptions, the amount of damage done to the material by fatigue stressing at various stress amplitudes can be expressed by:

$$\frac{n_1}{N_1} + \frac{n_2}{N_2} + \dots + \frac{n_r}{N_r} = \sum_{i=1}^{i=r} \frac{n_i}{N_i} = D \quad (1)$$

where

$n_i$  total number of cycles of stress applied to material at  $i$ th stress

$N_i$  number of cycles at  $i$ th stress alone that would cause failure

$D$  cumulative-damage ratio, a value of unity representing failure according to Miner

When only two stresses are considered, equation (1) becomes

$$\left( \sum n_H/N_H \right) + \left( \sum n_L/N_L \right) = D \quad (2)$$

where

$\sum n_H$  total number of cycles of higher stress

$\sum n_L$  total number of cycles of lower stress

$N_H$  cycles to failure at higher stress

$N_L$  cycles to failure at lower stress

$n_H$  cycles at high stress in a cycle pattern

$n_L$  cycles at low stress in a cycle pattern

For these tests  $N_H$  and  $N_L$  are averaged values of cycles to failure derived from the four tests to failure at the higher and lower stresses, respectively.

## RESULTS

### Tests of 0.064-Inch-Thick Alclad 75S-T6 Aluminum Alloy

Six hundred and seven specimens of 0.064-inch-thick alclad 75S-T6 aluminum alloy were tested in thirty-nine test groups and thirty-five different loading conditions. The results of these tests are shown in table 1. Table 2 is a summary of these results.

Nominal-stress-amplitude combinations of  $\pm 30,000$  and  $\pm 40,000$  psi,  $\pm 30,000$  and  $\pm 60,000$  psi,  $\pm 16,000$  and  $\pm 60,000$  psi,  $\pm 16,000$  and  $\pm 17,000$  psi, and  $\pm 16,000$  and  $\pm 30,000$  psi were used for the tests.

The cycle patterns were chosen from the equation

$$\epsilon = \frac{n_H/N_H}{\frac{n_H}{N_H} + \frac{n_L}{N_L}} \quad (3)$$

to cover a range of values of  $\epsilon$  and thus to show any systematic variation of  $D$  with different ratios of high-to-low cycles in a cycle pattern. Figure 7, taken from typical data, shows that there is no systematic variation with different ratios of high-to-low cycles.

The average value of  $D$  for similar tests (usually four) in a test group ranged from 0.603 to 1.440. The value of  $D$  for individual specimens ranged from 0.373 to 1.911. The average deviation of tests to failure at a single stress was of the same order as the average deviation for the cumulative-damage tests. Test groups 12, 13, 14, and 15 were tested at nominal stress levels of  $\pm 30,000$  and  $\pm 60,000$  psi with identical cycle patterns. Average values of  $D$  ranged from 0.805 to 0.879 for tests in which the low stress was applied first and from 0.729 to 0.896 for tests in which the high stress was applied first. The scatter of these values for the same cycle pattern suggests that four repetitions (of the sequence of four tests for each test group) are adequate to give consistent average values of  $D$ .

Effects of prior dynamic stressing of some aluminum alloys at one stress amplitude on the fatigue strength at a second stress amplitude have been investigated (refs. 14 to 16). The results show a pronounced increase in fatigue life for certain loading conditions. The cycle patterns of test groups 11, 22, 24, 25, 29, and 30 were especially selected to investigate these effects. In test groups 11, 22, 29, and 30, every specimen except one gave cumulative-damage ratios above unity for tests in which the higher stress was applied first. The average values of  $D$  ranged from 1.074 to 1.440 and the individual values of  $D$  ranged from 0.843 to 1.911;  $n_H$  ranged from 35.4 to 82.9 percent of the life of the material. There seems to be no systematic variation of  $D$  when the lower stress is applied first or for tests performed at nominal stress levels of  $\pm 16,000$  and  $\pm 17,000$  psi.

Test group 23 investigated the cumulative-damage effect of short bursts of a very high stress. These tests were performed at nominal stress levels of  $\pm 16,000$  and  $\pm 60,000$  psi. For the first group of cumulative-damage tests  $L-H_a$  (table 1(c)) the cyclic sequence was 100,000 cycles at low stress, plus 500 cycles at high stress, plus 100,000 cycles at low stress, plus 500 cycles at high stress, plus the remaining life of the specimen at the lower stress. The second group of cumulative-damage tests  $L-H_b$  followed the sequence of 100,000 cycles at the low stress plus 100 cycles at the high stress. This sequence was repeated until failure. The value of  $D$  was 0.806 and 0.663, respectively.

Figures 8(a) to 8(c) show the effect on  $D$  of the length of cycle pattern. For tests in which the higher stress was applied first an increase in the consecutive cycles applied tends to increase the cumulative-damage ratio. There seemed to be no effect on  $D$  for tests in which the lower stress was applied first.

Figure 9<sup>1</sup> presents the cumulative-damage ratios for all the tests. Figure 10 is an S-N diagram of the material. The points were plotted from the data summarized in table 2 on specimens tested to failure at one stress amplitude.

---

<sup>1</sup>The test groups in figure 9 are not listed in numerical order.

Tests of 0.032-Inch-Thick Alclad 24S-T3  
and Alclad 75S-T6 Aluminum Alloy

One hundred and ninety-eight specimens of 0.032-inch-thick aluminum alloy were tested in thirteen test groups (thirteen different loading conditions) at nominal-stress-amplitude combinations of  $\pm 16,000$  and  $\pm 30,000$  psi. The results of these tests are presented in table 3 and are summarized in table 4. Tests on groups 40 through 45 were made on alclad 24S-T3 and tests on groups 46 through 52 were made on alclad 75S-T6. Figure 11 shows that there is no appreciable variation in the cumulative-damage ratios obtained from the two materials.

The cycle patterns were chosen from equation (3) so that the values of  $D$  for the 0.032-inch material could be compared with those for the 0.064-inch material.

The average value of  $D$  for these tests varied from 0.568 to 1.218. The value of  $D$  for individual specimens in this series ranged from 0.381 to 1.422.

Figure 12 presents an S-N diagram of the materials used. The points were plotted from the data in table 3 for specimens tested at one stress amplitude.

DISCUSSION

A comparison of average values of the cumulative-damage ratio  $D$  for the 0.032-inch-thick material with a few average values for the 0.064-inch material is shown in table 5. There is no apparent variation of  $D$  with sheet thickness.

Table 5 also shows that, for test groups of comparable cycle patterns,  $D$  is about the same for tests performed at mean stresses of 0- and 20,000-psi tension.

The largest average cumulative-damage ratio obtained for a group of four similar specimens was 1.440 in test group 29 and the smallest, 0.568 in test group 41.

From the data of tables 2 and 4, the fatigue life can be predicted, using Miner's cumulative-damage ratio, to within 20 percent 72 percent of the time and to within 10 percent 40 percent of the time regardless of

- (1) The stress amplitude
- (2) The sheet thickness
- (3) The alloy
- (4) The mean stress

Although the present tests indicate relatively little deviation from a cumulative-damage ratio of 1 at failure, it must be remembered that all the tests have been conducted under conditions of nominally uniform stress. For specimens having stress concentrations it is likely that high tensile stresses will cause permanent set and result in beneficial residual stresses in the neighborhood of the stress concentration. For subsequent cycling at lower loads of the same type, an improvement in life may therefore be expected.

#### CONCLUDING REMARKS

Cumulative-fatigue-damage tests were made on 607 specimens of 0.064-inch-thick alclad 75S-T6 aluminum alloy in 35 different loading conditions and on 198 specimens of 0.032-inch-thick alclad 24S-T3 and alclad 75S-T6 aluminum alloy in 13 different loading conditions. The data presented indicate that, when the materials are stressed as described, the life can be predicted to within 20 percent 72 percent of the time and to within 10 percent 40 percent of the time, using the assumption that the damage is proportional to the ratio of the number of cycles applied at any stress to the number of cycles at the same stress that would cause failure.

There does not seem to be any systematic variation of the aforementioned conclusion with

- (1) The stress amplitudes used
- (2) The sheet thickness used
- (3) The alloy used
- (4) The mean stress applied

There appears to be an increase in the cumulative-damage ratio with an increase in cycle ratio for tests in which the higher stress was applied first. There seems to be no effect, however, for tests in which the lower stress was applied first. The cumulative-damage ratios for these tests were, in general, less than unity.

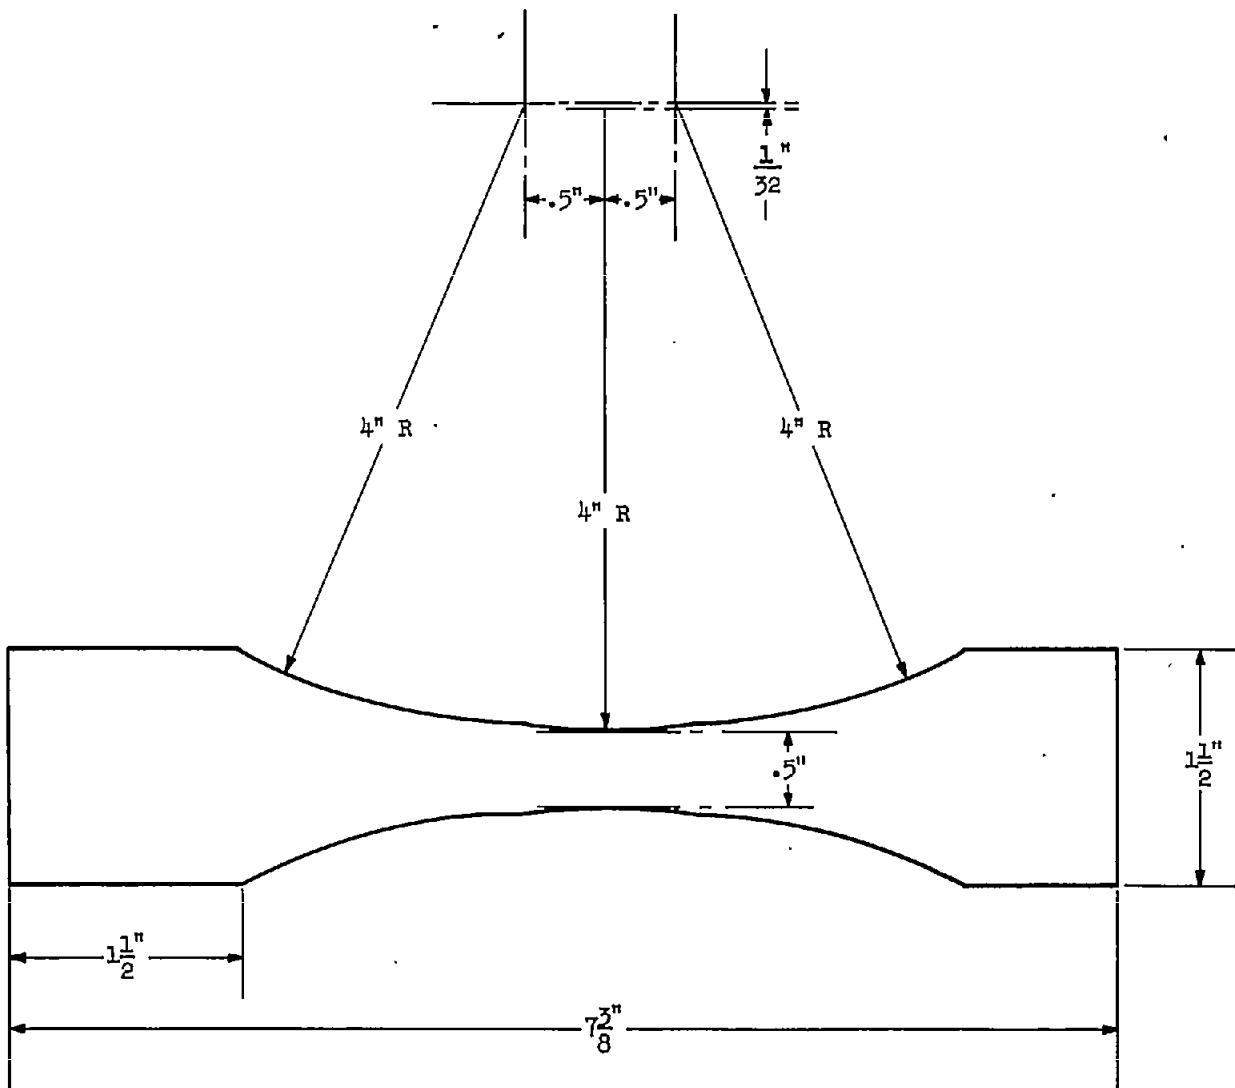

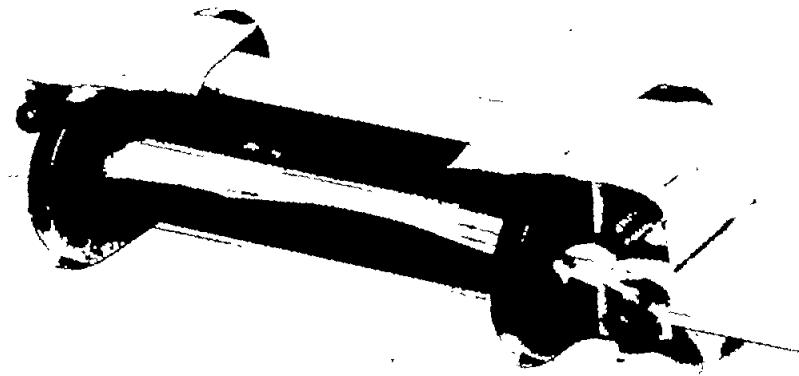

Figure 5.- Design of specimen. All dimensions are in inches.

L-87946  
Figure 6.- Typical specimen assembled in guides.

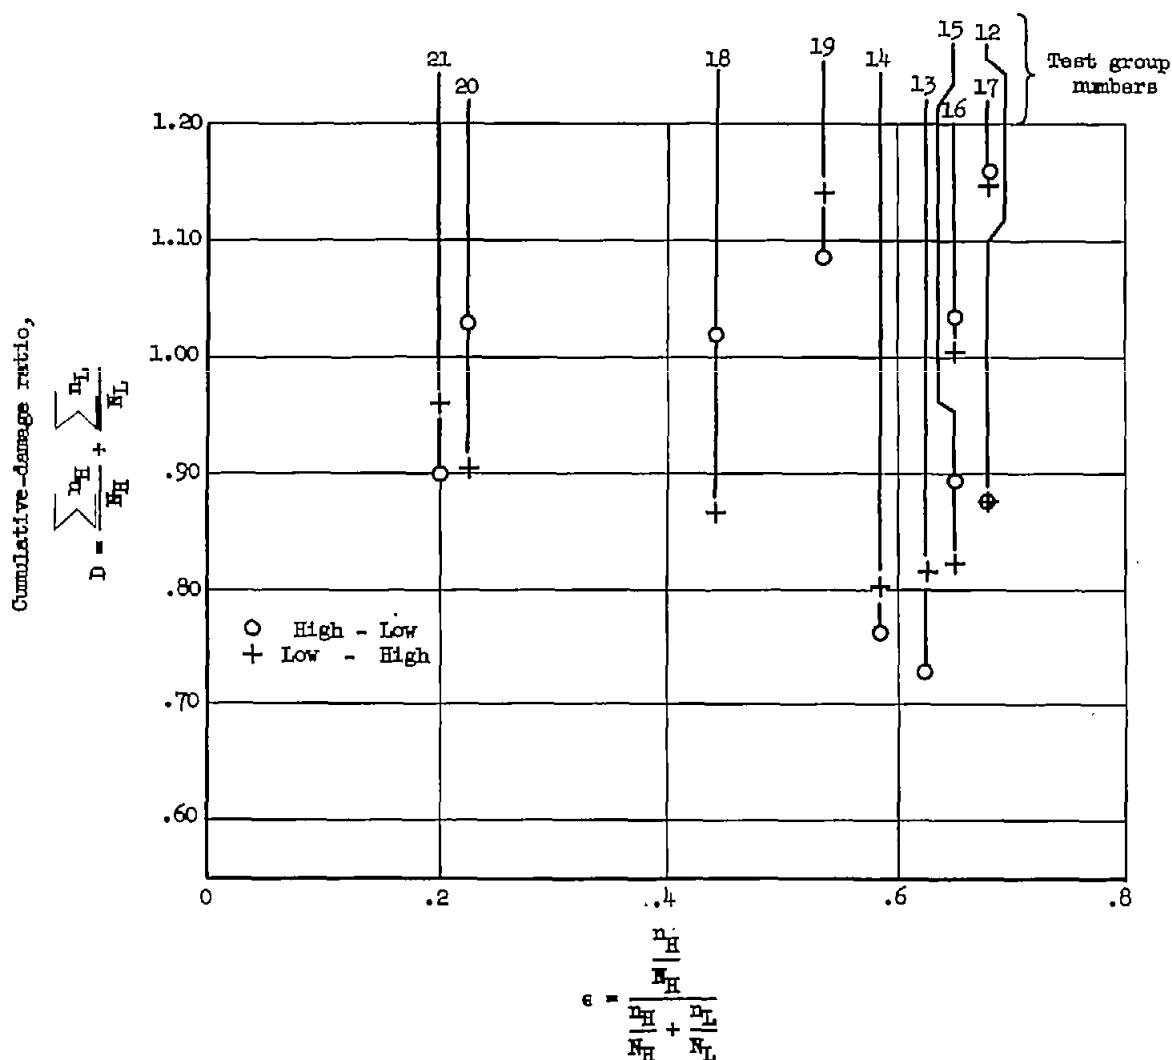

Figure 7.- Cumulative-damage ratio versus cycle-pattern ratio.

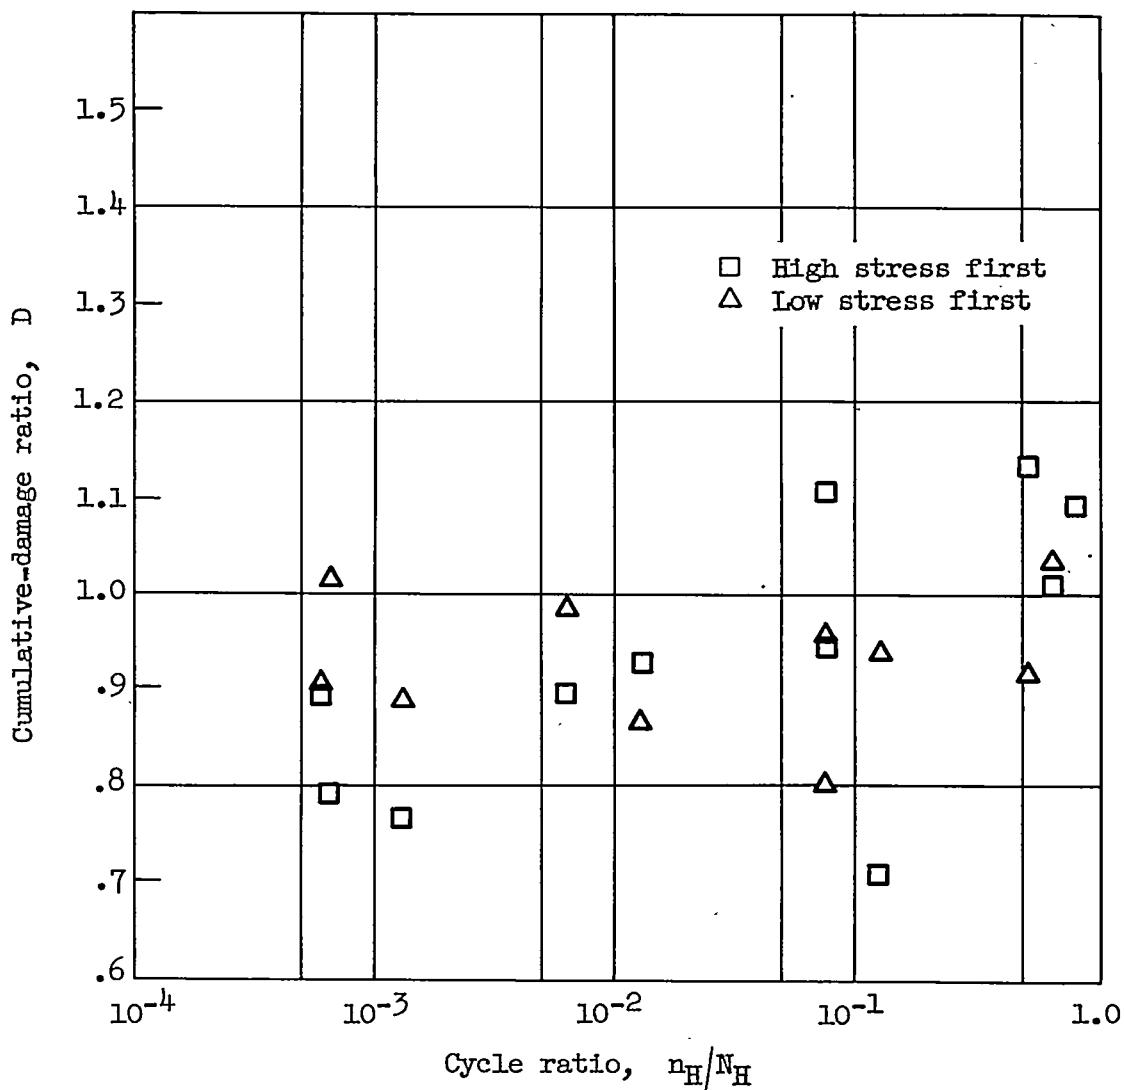

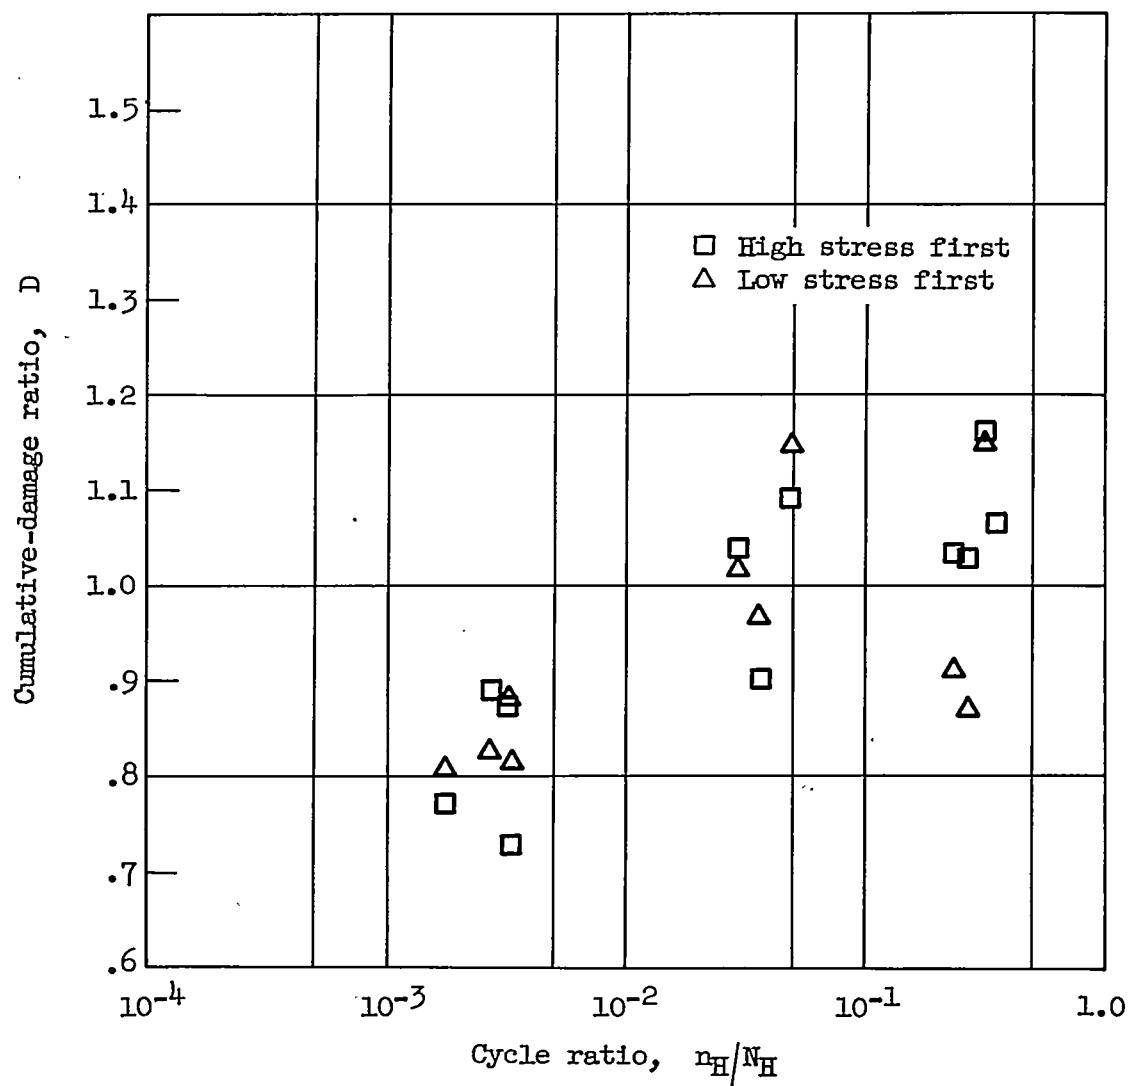

(a) Nominal stresses,  $\pm 30,000$  and  $\pm 40,000$  psi.

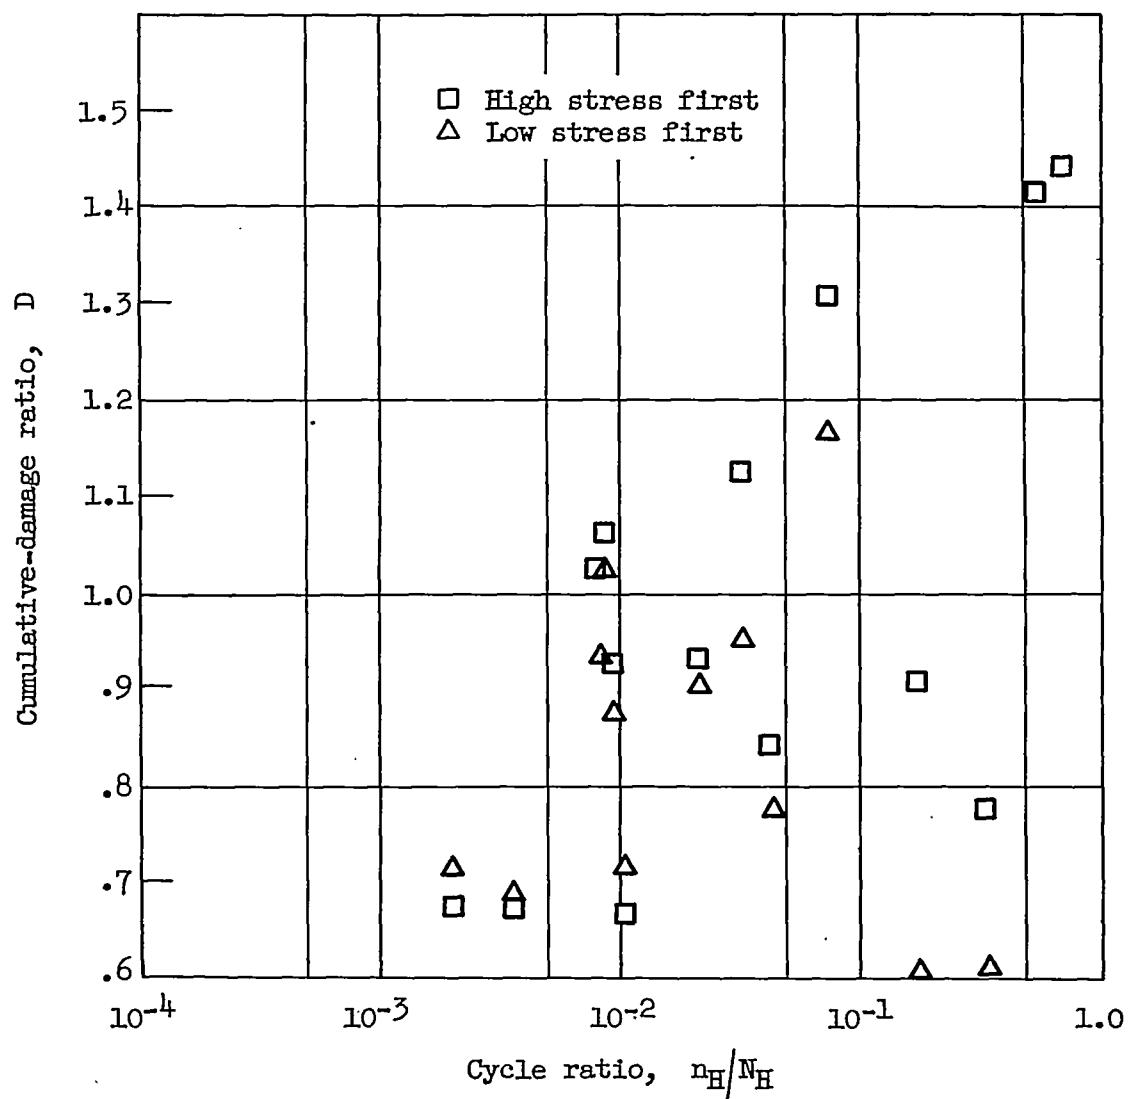

Figure 8.- Cumulative-damage ratio versus length of cycle pattern.

$D = \left( \sum n_H/N_H \right) + \left( \sum n_L/N_L \right)$  where  $n_H$  is the number of consecutive cycles applied at the higher stress,  $n_L$  is the number of consecutive cycles applied at the lower stress, and  $N_H$  and  $N_L$  are the averaged cycles to failure at the higher and lower stress levels, respectively.

(b) Nominal stresses,  $\pm 30,000$  and  $\pm 60,000$  psi.

Figure 8.- Continued.

(c) Nominal stresses,  $\pm 16,000$  and  $\pm 30,000$  psi.
